[1] A primary component of the observed recent climate change is the radiative forcing from increased concentrations of long-lived greenhouse gases (LLGHGs). Effective simulation of anthropogenic climate change by general circulation models (GCMs) is strongly dependent on the accurate representation of radiative processes associated with water vapor, ozone, and LLGHGs. In the context of the increasing application of the Atmospheric and Environmental Research, Inc. (AER), radiation models within the GCM community, their capability to calculate longwave and shortwave radiative forcing for clear sky scenarios previously examined by the radiative transfer model intercomparison project (RTMIP) is presented. Forcing calculations with the AER line-by-line (LBL) models are very consistent with the RTMIP line-by-line results in the longwave and shortwave. The AER broadband models, in all but one case, calculate longwave forcings within a range of  $-0.20$  to  $0.23 \text{ W m}^{-2}$  of LBL calculations and shortwave forcings within a range of  $-0.16$  to  $0.38 \text{ W m}^{-2}$  of LBL results. These models also perform well at the surface, which RTMIP identified as a level at which GCM radiation models have particular difficulty reproducing LBL fluxes. Heating profile perturbations calculated by the broadband models generally reproduce high-resolution calculations within a few hundredths  $\text{K d}^{-1}$  in the troposphere and within  $0.15 \text{ K d}^{-1}$  in the peak stratospheric heating near 1 hPa. In most cases, the AER broadband models provide radiative forcing results that are in closer agreement with high-resolution calculations than the GCM radiation codes examined by RTMIP, which supports the application of the AER models to climate change research.

### 1. Introduction

[2] A primary component of recent climate change is the radiative forcing caused by changes in concentration of the radiatively active greenhouse gases in the atmosphere. Radiative forcing is [Solomon *et al.*, 2007, p. 21] "...a measure of the influence a factor has in altering the balance of incoming and outgoing energy in the Earth-atmosphere system and is an index of the importance of the factor as a potential climate change mechanism." Between 1750 and 2005, the radiative forcing at the top of the atmosphere due to increases in concentration of carbon dioxide, methane and nitrous oxide was  $+1.66$ ,  $+0.48$ , and  $+0.16 \text{ W m}^{-2}$

respectively [Solomon *et al.*, 2007]. Halocarbons such as  $\text{CCl}_3\text{F}$  (CFC-11) and  $\text{CCl}_2\text{F}_2$  (CFC-12) have contributed an additional forcing of  $+0.34 \text{ W m}^{-2}$  since the mid-20th century resulting in a total forcing due to long-lived greenhouse gases (LLGHGs) of  $+2.64 \text{ W m}^{-2}$  with a margin of uncertainty of 10%. This forcing represents roughly 1% of the shortwave energy absorbed by the climate system and the longwave energy emitted by the Earth at the top of the atmosphere in a typical year, and the sign of the forcing indicates that the climate system is presently absorbing more energy than it releases. Accurate representation of these radiative processes in climate models is clearly essential to enhancing our ability to understand and to predict global climate change.

[3] Recent research has examined the radiative forcing calculated by several coupled atmosphere-ocean general circulation models (AOGCMs) that contributed to the Intergovernmental Panel on Climate Change (IPCC) Fourth Assessment Report (AR4) and by several reference line-by-line (LBL) radiative transfer models [Collins *et al.*, 2006] (hereinafter referred to as C06). The Radiative Transfer Model Intercomparison Project (RTMIP) conducted

<sup>1</sup>Atmospheric and Environmental Research, Inc., Lexington, Massachusetts, USA.

<sup>4</sup>Also at Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, USA.

by C06 defined eight clear sky calculations in which the LLGHGs were specified according to various forcing scenarios that were performed by the AOGCMs for the AR4. This intercomparison concluded that while there is excellent agreement among the LBL models, there are substantial differences in forcing among the AOGCMs and between the AOGCMs and LBL models of order  $0.5 \text{ W m}^{-2}$  or greater [Collins *et al.*, 2006]. The largest AOGCM forcing discrepancies were seen at the Earth's surface. Neglect of individual molecular absorbers (such as methane in the shortwave) in the AOGCMs and the radiative transfer methods utilized were both cited as reasons for the differences from the LBL codes.

[4] The RTMIP forcing results reported by C06 for the IPCC climate models do not include calculations with the radiation models [Clough *et al.*, 2005] that have been developed at Atmospheric and Environmental Research, Inc. (AER), with support from the Department of Energy (DOE) Atmospheric Radiation Measurement (ARM) Program. Radiance closure studies are a critical feature of these models that enhances their wider use in climate applications. These studies provide a continual evaluation of the models with surface, aircraft and satellite measurements to quantify and to improve their accuracy [e.g., Turner *et al.*, 2004]. This addresses the essential need to establish the accuracy of GCM radiation models through careful evaluation with measurements. This summary of radiative forcing results for the AER models following the RTMIP calculations is motivated by the wide use of the AER line-by-line model within the community and in particular by the increasing application of the AER correlated k distribution broadband models within the GCM community. This includes the operational use of RRTMG\_LW or SW in the ECMWF weather forecast system [Morcrette *et al.*, 2008], the NCEP global forecast system (GFS) model, the Weather Research and Forecasting (WRF) model, and the ECHAM5 climate model [Wild and Roeckner, 2006] among other applications. RRTMG is also being evaluated for use in the GFDL and NCAR climate models. Details of the AER radiation models and the source code are available at the AER radiative transfer web site (<http://www.rtweb.aer.com>).

## 2. Radiation Models

[5] LBLRTM is an accurate, efficient and highly flexible line-by-line radiative transfer model that continues to be extensively validated with measured atmospheric radiance spectra from the submillimeter to the ultraviolet [Clough *et al.*, 2005; Turner *et al.*, 2004]. LBLRTM includes all significant molecular absorbers and represents the effects of self-broadening and foreign-broadening from water vapor with the MT\_CKD\_v1.4 continuum model. It uses all parameters on the HITRAN 2004 database, and it includes the continua of carbon dioxide, oxygen, nitrogen, ozone as well as Rayleigh scattering extinction. The algorithmic accuracy of LBLRTM is 0.5%, and the limiting errors are generally attributable to the input line parameters and line shape. Integrated fluxes and heating rates are derived from LBLRTM radiance spectra with an independent program (RADSUM), which is also available at the AER radiative transfer web site. For the RTMIP calculations presented,

LBLRTM/RADSUM utilizes three angles (six streams) for flux integration.

[6] CHARTS (code for high-resolution accelerated radiative transfer with scattering) is a monochromatic plane-parallel radiative transfer model for the line-by-line calculation of radiances and fluxes at a single level for thermal and solar regimes in general scattering atmospheres [Moncet and Clough, 1997]. The atmosphere is treated as a vertically stratified medium in CHARTS, and individual layers are considered homogeneous in gaseous optical depth and in the cloud and aerosol optical properties. Molecular optical depths for the layers are provided by LBLRTM. Using the adding-doubling method, CHARTS efficiently treats multiple scattering for reference calculations of spectral radiances at single levels. Calculations with this model have been validated against high-resolution spectral radiance measurements [Mlawer *et al.*, 2000]. The CHARTS algorithm is applied here to the shortwave net flux forcing calculations at the three pressure levels considered by the RTMIP intercomparison.

[7] RRTM has been developed for both the longwave (LW) and shortwave (SW) regions as reference broadband radiative transfer models that closely reproduce line-by-line results [Mlawer *et al.*, 1997]. Absorption coefficients for the primary and minor molecular species required for the correlated k distribution method used by RRTM have been obtained from LBLRTM. Molecular absorbers included in RRTM are water vapor, carbon dioxide, ozone, methane, nitrous oxide, oxygen, nitrogen and the halocarbons in the longwave and water vapor, carbon dioxide, ozone, methane and oxygen in the shortwave. The water vapor continuum is based on CKD\_v2.4 in the versions of RRTM applied to this work, and molecular line parameters are based on HITRAN 2000 for water vapor and HITRAN 1996 for all other molecules. Extinction from aerosols, clouds and Rayleigh scattering are also included, and the discrete ordinates algorithm DISORT [Stamnes *et al.*, 1988] is used for multiple scattering calculations. Several optional cloud liquid and ice parameterizations are available that allow the specification of cloud fraction and cloud physical or optical properties, though the shortwave is limited to fully clear or overcast calculations. RRTM\_LW accuracy in clear sky relative to LBLRTM for flux is  $1.0 \text{ W m}^{-2}$  at all levels, and heating rates agree to within  $0.1 \text{ K d}^{-1}$  in the troposphere and  $0.3 \text{ K d}^{-1}$  in the stratosphere. RRTM\_SW accuracy in clear sky is  $1.0 \text{ W m}^{-2}$  for direct flux and  $2.0 \text{ W m}^{-2}$  for diffuse flux relative to line-by-line calculations. For the RTMIP calculations presented, RRTM\_LW utilizes four angles (eight streams) and RRTM\_SW/DISORT uses eight angles (16 streams) for flux integration.

[8] With the objective of providing a radiative transfer model that can be directly applied to GCMs [Iacono *et al.*, 2000, 2003] with an accuracy that is traceable to ARM and other measurements, RRTM has been modified to produce RRTMG. The former model retains the highest accuracy relative to line-by-line results for single-column calculations, and the latter provides better efficiency with minimal loss of accuracy for GCM applications. While RRTMG shares the same basic physics and absorption coefficients as RRTM, it incorporates several modifications to improve computational efficiency, to update the code formatting for

easier application to GCMs, and to represent subgrid-scale cloud variability. In particular, the total number of quadrature points (g points) used to calculate radiances in the longwave has been reduced from the standard 256 in RRTM\_LW (with 16 g points in each of the 16 spectral bands) to 140 in RRTMG\_LW (with the number of g points in each spectral band varying from 2 to 16 depending on the absorption in each band). In the shortwave, the number of g points has been reduced from the standard 224 in RRTM\_SW (with 16 in each of the 14 spectral bands) to a total of 112 in RRTMG\_SW. In addition, DISORT has been replaced with a two-stream radiative transfer solver [Oreopoulos and Barker, 1999] in RRTMG\_SW. Also, RRTMG has been fully reformatted for consistency between the longwave and shortwave and to incorporate modern FORTRAN90 functionality. Clear sky RRTMG\_LW accuracy relative to LBLRTM for flux is 1.5 W m<sup>-2</sup> at all levels, and heating rates agree to within 0.2 K d<sup>-1</sup> in the troposphere and generally 0.4 K d<sup>-1</sup> in the stratosphere. RRTMG\_SW accuracy in clear sky relative to RRTM\_SW is within 3 W m<sup>-2</sup> (about 0.3%) for flux at all levels, and heating rates agree to within 0.1 K d<sup>-1</sup> in the troposphere and 0.35 K d<sup>-1</sup> (about 1%) in the stratosphere. For the RTMIP calculations presented here, RRTMG\_LW and RRTMG\_SW utilize the single standard diffusivity angle (two streams) for flux integration, though RRTMG\_LW also incorporates a small modification of the diffusivity angle in some spectral bands that varies as a function of total column water vapor to improve fluxes and heating rates in profiles with high water vapor amounts.

[9] Because of the complexity of representing cloud overlap in the presence of multiple scattering, RRTM\_SW with DISORT is limited to calculations with clear or fully overcast conditions. This limitation has been addressed for RRTMG\_LW and SW with the addition of McICA, the Monte Carlo Independent Column Approximation [Barker

*et al.*, 2002; Pincus *et al.*, 2003], which is a statistical technique for representing subgrid-scale cloud variability including cloud overlap. This method represents cloud fraction by replacing the scalar cloud amount with a randomly sampled binary array dimensioned on g point. Depending on its binary cloud amount of zero or one, an individual g point is treated as fully clear or fully cloudy, respectively. Because of the highly variable contribution of each g point to the total absorption, this method introduces random noise to the cloudy calculation of radiance, but the result has been shown to be unbiased. This approach provides the flexibility to represent the vertical correlation of the clouds (i.e., cloud overlap) in some detail by imposing an assumed relation (such as random or maximum-random) among the binary cloud arrays across the vertical dimension. Cloud physical properties (ice and liquid water path and particle sizes) or cloud optical properties (optical depth) are also dimensioned on g point in each layer following the arrangement of the binary cloud fraction arrays, and these arrays are used in the radiative transfer to calculate total cloudy radiance. RRTMG is especially well suited to utilize McICA because of its relatively high number of g points. However, this feature is not applied in the clear cases examined here.

### 3. Radiative Forcing

[10] The radiative transfer calculations performed with the AER models follow the eight cases defined by C06, in which only the concentrations of the long-lived greenhouse gases were varied. Temperature, water vapor and ozone were specified by the standard midlatitude summer profile, and calculations were performed over 40 vertical layers from the surface to a height of 0.01 hPa. Neither aerosols nor clouds were considered in the RTMIP calculations reported here or by C06. Radiative forcings were calculated

as net flux differences between the C06 cases, and Table 1 lists the specific LLGHG concentration changes for each of the seven case differences examined. For example, the result for case 2a-1a is the forcing from increasing CO<sub>2</sub> from its value of 287 ppmv in 1860 AD to its value of 369 ppmv in 2000 AD, while case 2b-1a provides the forcing from doubling CO<sub>2</sub> from its 1860 value to 574 ppmv. Case 3b-3a shows the forcing from increasing CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O from their values in 1860 to 2000 as well as increasing the CFCs from zero to their present values. Other differences for cases 3a through 3d involve various changes in the LLGHGs. Case 4a-2b includes the effect of increasing water vapor in the whole column by 20% in the presence of doubled CO<sub>2</sub> as a proxy for the predicted increase in H<sub>2</sub>O in a warmer climate. The shortwave

forcing calculations with the AER models depart from the C06 RTMIP specification in that the former were performed over the 820–50000 cm<sup>-1</sup> (0.2–12.2 μm) spectral range with a solar constant of 1368.2 W m<sup>-2</sup>. The C06 calculations used a spectral range 0.2–5.0 μm and a reduced solar constant of 1360 W m<sup>-2</sup> to accommodate this spectral limit in the GCM radiation models studied by C06. The contribution of the 5.0–12.2 μm region to the total solar forcing for the cases examined is 0.01 W m<sup>-2</sup> or less, except for a 0.05 W m<sup>-2</sup> contribution to the total forcing in case 4a-2b at the surface.

[11] While the results for the IPCC GCMs and several LBL models were presented by C06 as intermodel averages and standard deviations, the radiative forcings for the AER codes are presented here for each model individually. The

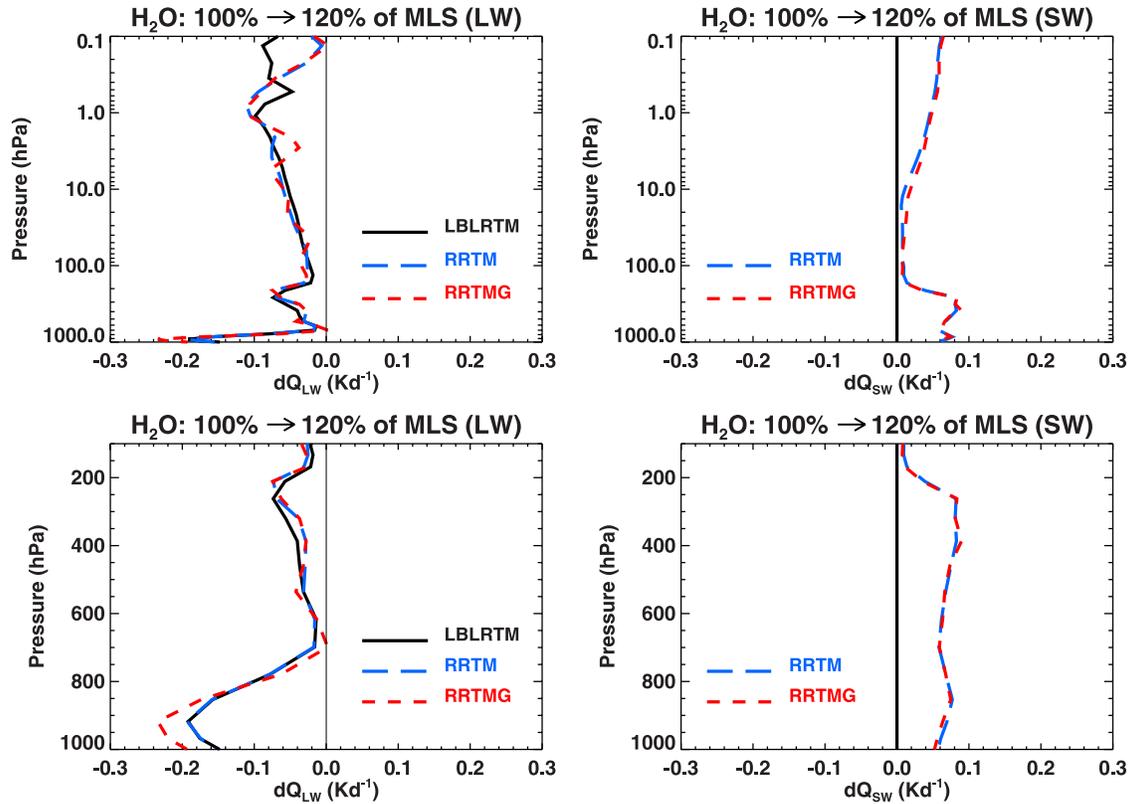

**Figure 1.** Heating rate profile changes from doubling the CO<sub>2</sub> concentration from 287 to 574 ppmv using the standard midlatitude summer profile for the (left) longwave and (right) shortwave from (top) the surface to 0.1 hPa and (bottom) the troposphere as calculated by the AER radiation models.

**Figure 2.** Heating rate profile changes from increasing the concentrations of  $\text{CO}_2$ ,  $\text{CH}_4$ ,  $\text{N}_2\text{O}$ , CFC-11, and CFC-12 from 1860 to 2000 values using the standard midlatitude summer profile for the (left) longwave and (right) shortwave from (top) the surface to 0.1 hPa and (bottom) the troposphere as calculated by the AER radiation models.

longwave radiative forcing based on net flux calculations at the top of the atmosphere, at 200 hPa, and at the surface is listed in Table 2 for LBLRTM\_v11.1, RRTM\_LW\_v3.2 and RRTMG\_LW\_v4.4. These can be compared with Table 8 in C06, which summarizes the GCM and line-by-line results for the longwave models examined in that study. For each case and at each of the three vertical levels, the radiative forcing calculated by LBLRTM is within  $0.06 \text{ W m}^{-2}$  of the mean LBL model result of C06. In most cases, the LBLRTM forcing is slightly higher than the C06 mean LBL forcing. The exception is case 3a-1a (the forcing from increasing the  $\text{CH}_4$  and  $\text{N}_2\text{O}$  concentrations from zero to their 1860 values), for which the LBLRTM result is slightly lower than the C06 mean LBL result. For all cases and at all three levels, the difference between the LBLRTM forcing and the mean C06 LBL result is generally less than the standard deviation of the C06 LBL forcing values. Radiative forcing differences at the top of the atmosphere between the AER broadband longwave models and LBLRTM range from  $-0.20$  to  $0.23 \text{ W m}^{-2}$  depending on the case with the exception of case 3a-1a for which RRTM\_LW and RRTMG\_LW are about  $0.55 \text{ W m}^{-2}$  lower than the line-by-line result. The later difference results from known minor deficiencies in the methane and nitrous oxide spectroscopic treatment in the broadband models, which is being addressed for future versions of these models. Although these differences are consistent with the differences between the mean GCM and LBL results

( $-0.35$  to  $0.17 \text{ W m}^{-2}$ ) shown by C06, it should be noted that the standard deviation of radiative forcing at the top of the atmosphere for the C06 GCM models varies from  $0.13$  to  $0.82 \text{ W m}^{-2}$  among the seven forcing cases. This suggests that some of the individual GCM model differences in the C06 study are considerably larger than the mean difference. At 200 hPa, the AER broadband model differences from LBLRTM range from  $-0.17$  to  $0.22 \text{ W m}^{-2}$  in all cases except for a forcing difference of  $0.35 \text{ W m}^{-2}$  for case 3a-1a. The mean C06 GCM model forcings at this level have a range of  $-0.42$  to  $0.06 \text{ W m}^{-2}$  in difference from the mean C06 LBL result and a range in forcing standard deviation of  $0.15$  to  $0.73 \text{ W m}^{-2}$ . At the surface, the AER broadband models perform especially well relative to LBLRTM with differences of  $0.11 \text{ W m}^{-2}$  or less in all cases, except for a difference of  $0.37 \text{ W m}^{-2}$  between RRTMG\_LW and LBLRTM in case 4a-2b (the forcing from increasing water by 20% with doubled  $\text{CO}_2$ ). By contrast, the difference in mean forcing for the GCM and LBL models examined by C06 varies from  $-0.52$  to  $0.67 \text{ W m}^{-2}$  at the surface across the seven cases. The standard deviation of surface longwave forcing among the C06 GCM models ranges from  $0.13$  to  $0.87 \text{ W m}^{-2}$ . The impact of the water vapor continuum change between LBLRTM (MT\_CKD\_1.4) and RRTM/RRTMG (CKD\_2.4) on case 4a-2b is  $0.01 \text{ W m}^{-2}$  or less at the top of the model and at 200 hPa, and it reduces the forcing by about  $0.1 \text{ W m}^{-2}$  at the surface (though the

**Figure 3.** Heating rate profile changes from increasing the water vapor concentration in the standard midlatitude summer profile in all layers by 20% with doubled  $\text{CO}_2$  (574 ppmv) in all calculations for the (left) longwave and (right) shortwave from (top) the surface to 0.1 hPa and (bottom) the troposphere as calculated by the AER radiation models.

impact is as large as  $0.3 \text{ W m}^{-2}$  in the middle troposphere). Finally, it is notable that the AER accelerated broadband model, RRTMG, performs well relative to RRTM in the longwave with differences generally less than  $0.05 \text{ W m}^{-2}$  except for case 4a-2b, where differences are  $0.1 \text{ W m}^{-2}$  at the tropopause and above and  $0.37 \text{ W m}^{-2}$  at the surface.

[12] The shortwave radiative forcing results are summarized in Table 3 for CHARTS\_v4.03, RRTM\_SW\_v2.7 and RRTMG\_SW\_v3.5. The CHARTS calculations used optical depths derived from LBLRTM\_v11.1. These results can be compared with Table 9 in C06, which summarizes the GCM and line-by-line results for the shortwave models examined in that study. For each case and at each of the three vertical levels, the radiative forcing calculated by CHARTS is within  $0.05 \text{ W m}^{-2}$  of the mean LBL model result of C06, except for case 4a-2b. In the latter case, CHARTS forcings are  $0.08 \text{ W m}^{-2}$  lower at 200 hPa and  $0.37 \text{ W m}^{-2}$  lower at the surface than the mean C06 line-by-line result. CHARTS calculations were also performed for the truncated  $0.2\text{--}5 \mu\text{m}$  spectral range used by the RTMIP shortwave models, and for this range CHARTS is within  $0.06 \text{ W m}^{-2}$  at 200 hPa and  $0.32 \text{ W m}^{-2}$  at the surface of the mean C06 LBL result in case 4a-2b. At the top of the atmosphere, radiative forcing differences between the AER broadband models and CHARTS range from  $-0.10$  to  $0 \text{ W m}^{-2}$  in all cases. Since RRTM\_SW and RRTMG\_SW include methane and nitrous oxide, which were not treated in the C06 GCM shortwave models, the

former models provide an improved result in cases that included these gases. At 200 hPa, the AER broadband model forcing differences from CHARTS range from  $-0.16$  to  $0.04 \text{ W m}^{-2}$  over all cases. The difference in the C06 mean GCM and mean LBL model forcings at this level range from  $-0.13$  to  $0.35 \text{ W m}^{-2}$  and a forcing standard deviation range of  $0.09$  to  $0.28 \text{ W m}^{-2}$ . Finally, at the surface the AER broadband model forcing differences from CHARTS range from  $0.02$  to  $0.38 \text{ W m}^{-2}$  over all cases except for a  $0.59 \text{ W m}^{-2}$  difference in case 3a-1a. The mean model forcing differences between the C06 GCM and LBL results at this level range from  $-0.50$  to  $0.98 \text{ W m}^{-2}$ , and the forcing standard deviation ranges from  $0.46$  to  $1.40 \text{ W m}^{-2}$ . This illustrates the significant improvement in shortwave forcing provided by the AER broadband models for the C06 RTMIP cases, especially at the surface, though further improvements are being investigated.

#### 4. Heating Rates

[13] Heating rate profiles are also affected by changes in LLGHGs through the impact on the net flux divergence. For example, doubling the concentration of carbon dioxide increases absorption of upwelling longwave radiation and reduces the upward longwave flux at the tropopause by about  $4 \text{ W m}^{-2}$ . Emission of downward longwave radiation increases by as much as  $4 \text{ W m}^{-2}$  in the middle troposphere and by about  $2 \text{ W m}^{-2}$  at the tropopause and surface. This

results in a decrease in net flux divergence in the lower troposphere and an increase in longwave radiative heating of up to  $0.1 \text{ K d}^{-1}$  at these levels. The change in the longwave heating rate profile from doubling the  $\text{CO}_2$  concentration from its 1860 amount is shown in Figure 1 (left) for the AER line-by-line and broadband radiation models. In this and subsequent figures, results are shown from the surface to 0.1 hPa in the top plots and from the troposphere up to 100 hPa in the bottom plots. In the stratosphere, the net flux divergence is increased, which results in a substantial reduction in longwave heating (enhancement in longwave cooling) at the 1 hPa level. In general, the AER broadband models very closely reproduce the changes in heating rate calculated by LBLRTM throughout the column. The largest departures of about 10% occur at and just below the stratospheric peak in longwave cooling. Changes in the shortwave heating profile for the doubled  $\text{CO}_2$  forcing case are shown in Figure 1 (right) for the two AER broadband models only. Shortwave heating rate calculations with CHARTS for the full profile were not performed because of the excessive computational effort required. RRTM and RRTMG generate very similar results with the exception of differences of a few hundredths  $\text{K d}^{-1}$  just below the tropopause and near the 1 hPa peak in stratospheric heating. The ability of the AER broadband models to reproduce the line-by-line forcing in radiative heating throughout most of the column is noticeably better than the C06 GCM radiation models. As shown in Figure 10 of C06, the GCM models studied in RTMIP generate results that vary considerably with some closely reproducing the line-by-line profile of heating rate perturbations while others oscillate around it by as much as  $0.1 \text{ K d}^{-1}$ . Similar conclusions can be drawn from the other RTMIP cases.

[14] Perturbations in the heating rate profiles from increasing the LLGHG concentrations from their 1860 to 2000 values (case 3b-3a) as calculated by the AER models are shown in Figure 2. Once again, the broadband models closely reproduce the change in heating calculated by LBLRTM in the longwave (Figure 2, left) through most of the vertical regime. Notable deviations include a roughly 10% overestimate of the increase in longwave cooling at the 1 hPa level by the broadband models and small differences of  $0.01 \text{ K d}^{-1}$  or less in the troposphere. In the shortwave (Figure 2, right), the broadband models produce nearly identical changes in heating throughout the profile with the largest difference of  $0.01 \text{ K d}^{-1}$  occurring just below the tropopause.

[15] Heating rate profile changes that result from increasing water vapor by 20% in the presence of doubled carbon dioxide are shown for the AER models in Figure 3. In the longwave (Figure 3, left), RRTM very closely reproduces the LBLRTM result in the lower troposphere, with RRTMG differing from the line-by-line calculation by no more than  $0.05 \text{ K d}^{-1}$  in the layers near surface. Above the middle troposphere, the two broadband models are nearly identical with differences from LBLRTM of a few hundredths  $\text{K d}^{-1}$  or less. The increase in water vapor enhances longwave cooling at all levels. In the shortwave, the two broadband models produce essentially identical results and increase shortwave heating in the troposphere by just under  $0.1 \text{ K d}^{-1}$  with generally smaller heating increases in the stratosphere. By contrast, Figure 13 in C06

shows that the heating perturbations for this case among the RTMIP GCM models differ by up to  $0.1 \text{ K d}^{-1}$  at various levels in the troposphere in the longwave and shortwave. Slight differences of a few hundredths  $\text{K d}^{-1}$  in heating rate are also apparent among the C06 line-by-line models. In the shortwave, the AER broadband heating rate calculations in Figure 3 are in excellent agreement with the C06 solar line-by-line model results.

## 5. Conclusions

[16] This paper summarizes the result of producing the clear sky radiative forcing calculations of the Radiative Transfer Model Intercomparison Project (RTMIP) of Collins *et al.* [2006] with the AER radiation models. The wide use by the community of the line-by-line model, LBLRTM, and the increasing use of the broadband correlated k distribution models RRTM and RRTMG for single-column and GCM applications, respectively, has motivated this comparison of the AER models to the line-by-line and IPCC AR4 models examined in the RTMIP experiment. Radiative forcing by individual long-lived greenhouse gases since the mid-18th century is on the order of  $1 \text{ W m}^{-2}$  or less. Therefore, highly accurate radiative transfer in GCMs is essential to model effectively the radiative contribution of LLGHGs to global climate change.

[17] In general, LBLRTM and CHARTS calculate radiative forcings that are in close agreement with the line-by-line models studied by C06, and in most cases the AER broadband models calculate forcings that are in better agreement with the line-by-line results than the mean of the C06 GCM radiation models. Among the seven cases and three levels studied (top of the atmosphere, 200 hPa, and surface), LBLRTM longwave forcings differ by  $0.06 \text{ W m}^{-2}$  or less from the mean C06 line-by-line model result, and the differences are generally less than the standard deviation of the latter models within each case. In all but one case, the LBLRTM forcing is slightly higher than the C06 mean line-by-line model forcing. In the shortwave, CHARTS forcings are within  $0.05 \text{ W m}^{-2}$  of the mean C06 line-by-line result, except for slightly larger differences in the case with increased water vapor.

[18] In all cases except one, the AER broadband models calculate longwave forcings that are within a range of  $-0.20$  to  $0.23 \text{ W m}^{-2}$  of LBLRTM, and more than half of the results are within  $0.10 \text{ W m}^{-2}$ . The primary exception is the case in which the concentrations of methane and nitrous oxide were increased from zero to their 19th century values, in which RRTM and RRTMG produce  $0.55 \text{ W m}^{-2}$  less forcing than the line-by-line result at the top of the atmosphere and  $0.35 \text{ W m}^{-2}$  less forcing at the tropopause. Although the cause of this discrepancy in RRTM and RRTMG is being investigated and corrected, it should be noted that this case among those considered by RTMIP is the scenario that is least relevant to analyses of recent climate change. By contrast, the mean longwave forcing calculated by the C06 GCM models differs from the line-by-line calculations over a range from  $-0.52$  to  $0.67 \text{ W m}^{-2}$ , with the largest discrepancies at the surface, and about one third of the mean results are within  $0.10 \text{ W m}^{-2}$ . In the shortwave, since the RTMIP GCM shortwave models did not include methane and nitrous oxide as noted by C06, the

AER broadband models, which do include these gases, provide forcing calculations that are more comparable to the higher resolution models in most cases. In all cases except one, the AER broadband models calculate shortwave forcings within a range of  $-0.16$  to  $0.38 \text{ W m}^{-2}$  of CHARTS. As in the longwave, the exception occurs for the case in which methane and nitrous oxide are increased from zero to 19th century values where the broadband model forcings are  $0.59 \text{ W m}^{-2}$  lower than the line-by-line result. By contrast, the mean shortwave forcing calculated by the C06 GCM models differs from the line-by-line calculations over a range from  $-0.50$  to  $0.98 \text{ W m}^{-2}$ . Finally, the surface was identified by C06 as the level at which the largest discrepancies occur between the RTMIP AOGCMs and LBL models, and that study noted that particular attention should be given to model evaluation at this level. This analysis shows that the AER broadband models perform especially well at the surface relative to line-by-line calculations in the longwave. Although some discrepancies remain in the shortwave that are being investigated, significant improvement is noted relative to the C06 GCM shortwave models.

[19] Changes in LLGHGs impact radiative heating profiles as well as fluxes, and the AER broadband models calculate heating perturbations for the RTMIP cases that are generally very consistent with LBL model calculations. In most cases in the longwave, differences between the broadband and line-by-line model heating rates are within a few hundredths  $\text{K d}^{-1}$  in the troposphere and  $0.15 \text{ K d}^{-1}$  in the stratospheric peak. Shortwave heating profiles were not calculated with the AER LBL model for this study, but the AER broadband heating rate perturbations are in excellent agreement with the C06 solar LBL model calculations. The AER radiation models undergo continual validation with measurements or evaluation against higher resolution models, and this intercomparison of radiative forcing calculations demonstrates their consistency, their accuracy relative to other widely used models, and their suitability for an extensive range of research and climate change applications.
